<https://homepages.cwi.nl/~stevens/mastermath/2021/>

# Some preliminaries

# Cost of algorithms

## Time complexity

= runtime

= number of unit operations

(unit: e.g. bit operation, cpu instruction, function call)

## Memory complexity

= amount of unit storage (unit: e.g. bit, byte, block)

## Asymptotic complexity functions

Parameter  $n$  (bitlength of the input / security parameter)

Definitions:

We write  $f(n) = O(g(n))$  if  
 $|f(n)| \leq M g(n)$  for all  $n \geq n_0$  (for some  $M, n_0$ )

(also the called order of the function,  
only the asymptotically fastest growing term is relevant)

$$poly(n) := \{f(n): \mathbb{R} \rightarrow \mathbb{R} \mid f(n) = O(n^d), d \in \mathbb{N}\}$$

(set of all functions that are asymptotically bounded  
by some polynomial)

$$f, g \in poly(n) \Rightarrow f + g, f \cdot g, f \circ g \in poly(n)$$

## Probabilistic algorithms $A(x)$

Uses random coins, non-deterministic

For fixed input, output has probability distribution

PPT := Probabilistic Polynomial-Time

### Notation

$x \stackrel{r}{\leftarrow} \mathcal{X}$  randomly sample from  $\mathcal{X}$

assume uniform distribution if  $\mathcal{X}$  is set

$\Pr[\textit{event}]$  = probability event happens

$E[X]$  = the expected value for random variable  $X$

Cryptographic constructions must asymptotically be

efficient: construction is PPT

secure: attacks should not be PPT

then for any desired gap factor  $G$  (e.g.  $G = 2^{128}$ )

there exists a  $n_0$  such that for all  $n \geq n_0$

cost of attack  $\geq G \times$  cost of construction

# Success probability for attacks $A$

= probability algorithm outputs correct solution  $y \in Sol(x)$

$$p_{succ}^A(x) := \Pr[y \leftarrow A(x) \wedge y \in Sol(x)]$$

Negligible success probability:

$$negl(n) := \{f: \mathbb{R} \rightarrow \mathbb{R} \mid \forall d \in \mathbb{N} : \lim_{n \rightarrow \infty} f(n) \cdot n^d = 0\}$$

negligible functions go to 0 very quickly,  
even when multiplied by any arbitrary polynomial function

E.g.: key guessing attack

- Simply try  $R$  random secret keys of  $n$  bits
- Finds correct key with probability  $R \cdot 2^{-n}$
- Should be negligible
  - In concrete sense:  
so unlikely one can disregard this attack
  - As in asymptotic sense:  
 $R \cdot 2^{-n} \in negl(n)$  if  $R \in poly(n)$

# One-Time Pad

# Symmetric Encryption Schemes

Send message secretly from sender to receiver

Using pre-shared secret key  $K$  (unknown to adversary)

Sender encrypts plaintext  $P$  to ciphertext  $C$

Keyspace  $\mathcal{K}$ , plaintext space  $\mathcal{P}$ , ciphertext space  $\mathcal{C}$

Function  $E_K: \mathcal{P} \rightarrow \mathcal{C}$  for  $K \in \mathcal{K}$

$$C = E_K(P)$$

Receiver uses corresponding decryption to obtain plaintext  $P$

$$P = D_K(C)$$

$$D_K: \mathcal{C} \rightarrow \mathcal{P}$$

Goals:

Correctness:  $D_K(E_K(P)) = P$  for all  $K, P$

Secrecy: without key  $K$

“no information is learned from  $C$  about message  $l$   
(formalization comes later)

# One-Time Pad (OTP)

For any  $l \in \mathbb{N}$ :

$$\mathcal{K}_l = \mathcal{P}_l = \mathcal{C}_l = \{0,1\}^l \approx \mathbb{F}_2^l$$

$$E_K(P) := P \oplus K$$

$$D_K(C) := C \oplus K$$

Requires  $K$  uniformly random selected

Key, and Plain- and ciphertext have equal length

$$0 \oplus 0 = 1 \oplus 1 = 0$$

$$1 \oplus 0 = 0 \oplus 1 = 1$$

Addition in  $\mathbb{F}_2$

Only encryption method providing **perfect secrecy**  
no statistical correlation between cipher- and plaintext  
if key is unknown

$\Rightarrow$  no information can be learned  
even with  $\infty$  computing power

$$\Pr_{\mathbf{K}}[C = P \oplus K] = \Pr_{\mathbf{K}}[K = P \oplus C] = 2^{-l}$$

Given  $C$ , every plaintext is equally likely

Given  $P$ , every ciphertext is equally likely

# One-Time Pad issues

Perfect secrecy, but ...

Perfect secrecy is broken if

Key  $K$  is not kept secret

$K$  was not selected uniformly at random from  $\mathcal{K}_l$

Key  $K$  is reused for two messages

attacker learns:  $C_1 \oplus C_2 = P_1 \oplus P_2$

Also **malleable!**

1. Sender encrypts  $P = \text{"I owe you 10\$"}$

2. Attacker intercepts  $C = K \oplus P$

$$\begin{aligned} \text{Let } D &= \text{"I owe you 10\$"} \oplus \text{"I owe you 5k\$"} \\ &= \text{"_____10_"} \oplus \text{"_____5k_"} \end{aligned}$$

Attacker doesn't even need to know the actual text,  
only the position and value of the change

3. Attacker sends  $C' = C \oplus D$  to receiver

4. Receiver obtains  $C'$  and decrypts:

$$P' = K \oplus C' = P \oplus D = \text{"I owe you 5k\$"}$$

# Stream Ciphers

# Stream ciphers

Operates very similar to One-Time Pad:  
simply XOR message with long key stream

$$C := P \oplus \tilde{K}$$

Except: long key stream  $\tilde{K}$  is generated from  
short pre-shared key  $K$

Short key size:  $k$  bits,  $\mathcal{K} = \{0,1\}^k$

Large internal state:  $s$  bits,  $S_i \in \{0,1\}^s$

Arbitrary long plain- and ciphertext:  $\mathcal{C} = \mathcal{P} = \{0,1\}^*$

1. Initialization:

$$S_0 := \text{Init}(K)$$

2. Step update for bit  $i$

$$(S_{i+1}, O_i) := \text{Update}(S_i)$$

3. Encrypt bit  $i$

$$C_i := P_i \oplus O_i$$

4. Repeat 2-3 for  $i = 0, \dots, |P| - 1$

Asynchronous version (to recover from missed  $C_j$ )

$$(S_{i+1}, O_i) := \text{Update}(S_i, C_{i-1}, \dots, C_{i-l})$$

## No perfect secrecy

Only  $2^k$  possible long key streams

For each plaintext, only  $2^k$  possible ciphertexts

For each ciphertext, only  $2^k$  possible plaintexts

For very long ciphertexts (with `meaningful` plaintext)

It's theoretical possible to try every key

$2^k - 1$  attempts should lead to `garbage`

The right key should lead to a `meaningful` plaintext

Hence, security must be computational

## Computational Security Properties for Stream Ciphers:

### Key recovery hardness

Given long keystream  $\tilde{K}$  hard to recover key  $K$

### State recovery hardness

Given long keystream  $\tilde{K}$  hard to recover a state  $S_i$

### Indistinguishability

Attacker cannot distinguish between

a random long keystream  $\tilde{K}$  and

a uniformly random bitstring of same length

Attacks

Property

# Indistinguishability

Security parameter: key size  $k$  (and state size:  $l$ )

Attacker: distinguisher algorithm  $A$

Gets access to  $\mathcal{O}$ :

Either, **stream cipher oracle**:  $\mathcal{O}_{sc}$

Selects  $K \xleftarrow{r} \{0,1\}^k$  uniformly at random

Outputs  $O_i$  on  $i$ -th query

Or, **random oracle**:  $\mathcal{O}_{ur}$

Outputs random  $O_i \xleftarrow{r} \{0,1\}$  on  $i$ -th query

Does not know which of the two it gets access to!

Returns either 0 or 1

think of the output as it's guess: stream cipher or random

Stream cipher is  $(d(k), c(k), \epsilon(k))$ -indistinguishable

if:  $|\Pr[A^{\mathcal{O}_{sc}} = 1] - \Pr[A^{\mathcal{O}_{ur}} = 1]| \leq \epsilon(k)$

for all distinguishers  $A$  that:

read at most  $d(k)$  bits from oracle

perform at most  $c(k)$  operations

*Concrete security*

$$d(k), c(k) := 2^{\min(k,l)}$$
$$\epsilon(k) := 2^{-128}$$

*Asymptotic security*

$$d(k), c(k) := \text{poly}(k)$$
$$\epsilon(k) := \text{negl}(k)$$

*Information-theoretic security*

Impossible:  $c(k) := \infty$

# Generic attacks

Generic Key recovery attack given target keystream  $\tilde{T}$

1. Walk over the search space  $K \in \{0,1\}^k$
2. Generate keystream  $\tilde{K}$  with same length as  $\tilde{T}$
3. If  $\tilde{K} = \tilde{T}$  then return  $K$
4. if no such  $K$  then return  $\perp$

Time complexity:  $O(2^k)$

Generic State recovery attack given target keystream  $\tilde{T}$

1. Walk over the search space  $S_0 \in \{0,1\}^l$
2. Generate keystream  $\tilde{K}$  with same length as  $\tilde{T}$
3. If  $\tilde{K} = \tilde{T}$  then return  $S_0$
4. If no such  $S_0$  then return  $\perp$

Time complexity:  $O(2^l)$

Generic distinguishing attack

From generic key recovery attack or state recovery attack:

Return 0 if recovery attack returns  $\perp$ , and 1 otherwise

Time complexity:  $O(2^{\min(k,l)})$

# Stream Cipher Malleability

Again Stream Ciphers only provide secrecy

As ciphertexts can be precisely modified:

1. Sender encrypts  $P = \text{"I owe you 10\$"}"$
2. Attacker intercepts  $C = K \oplus P$   
Let  $D = \text{"_____10_"} \oplus \text{"_____5k_"}"$
3. Attacker sends  $C' = C \oplus D$  to receiver
4. Receiver obtains  $C'$  and decrypts:  
 $P' = K \oplus C' = P \oplus D = \text{"I owe you 5k\$"}"$

## Key reuse

Key  $K$  must not be reused for two messages  
otherwise attacker learns:  $C_1 \oplus C_2 = P_1 \oplus P_2$

Common trick:

Split  $k$  bit key into  $k_1$  bits secret key and  $k_2$  bits (public) nonce

Pre share single secret key  $K_1 \in \{0,1\}^{k_1}$

Reuse  $K_1$  by choosing different (public) values  $K_2 \in \{0,1\}^{k_2}$

E.g.: maintain counter  $K_2$  with  $k_2 \geq 32$

Or choose random  $K_2$ , then  $k_2 \geq 128$

# Block Ciphers

- Block ciphers work differently from the one-time pad and stream ciphers
  - Only encrypts fixed-size blocks as a whole (not per bit)
  - Let security parameter  $n$
  - Key space  $\mathcal{K}(n)$  and block space  $\mathcal{M}(n)$  (e.g.,  $\{0,1\}^n$ )
  - $Enc: \mathcal{K}(n) \times \mathcal{M}(n) \rightarrow \mathcal{M}(n)$  such that
    - $Enc_K: \mathcal{M}(n) \rightarrow \mathcal{M}(n)$  is a permutation for all  $K \in \mathcal{K}(n)$
    - $Dec_K := Enc_K^{-1}$  is efficiently computable
- Note:  $n$  is typically omitted:  $\mathcal{K}, \mathcal{M}$

# Generic attacks

## Generic key recovery attack model

No relevant key stream to provide to attacker

Instead list of plaintext + ciphertext pairs:  $(P_1, C_1), (P_2, C_2), \dots$

Which pairs?

Known plaintext attack: random plaintexts

Chosen plaintext attack: attacker may choose  $P_i$

...

## Generic key recovery attack

1. Query  $l$  pairs  $(P_1, C_1), \dots, (P_l, C_l)$
2. Walk over search space  $K \in \mathcal{K}$
3. If  $C_i = Enc_K(P_i)$  for  $i = 1, \dots, l$  then return  $K$
4. Otherwise, if no such  $K$ , return  $\perp$

Complexity:  $O(|\mathcal{K}|)$

Note: Even if there are  $l$  pairs to check in total  
The first is very likely to fail and the key candidate is rejected  
so most times we only have to check 1 pair

# Generic 1-out-of- $L$ key recovery attack

Assume  $L$  users with different keys  $K_1, \dots, K_L$

Attacker succeeds if it finds 1 key

## Generic attack

1. Chooses  $l$  plaintexts  $P_1, \dots, P_l$
2. Queries encryptions for each user:  
$$C_{i,j} = \text{Enc}_{K_j}(P_i) \text{ for } i = 1, \dots, l \text{ and } j = 1, \dots, L$$
3. Walks over search space  $K \in \mathcal{K}$
4. Compute  $\tilde{C}_1 = \text{Enc}_K(P_1)$
5. For  $j$  such that  $C_{1,j} = \tilde{C}_1$  do
6. If  $C_{i,j} = \text{Enc}_K(P_i)$  for  $i = 2, \dots, l$  then return  $K$
7. Otherwise, return  $\perp$

Every key guess has success probability  $L/|\mathcal{K}|$

Complexity:  $O(|\mathcal{K}|/L)$

Speed up by factor  $L!$

## Attacks with precomputation

There are attacks that cost  $O(|\mathcal{K}|)$  or more in total

But  $< O(|\mathcal{K}|)$  per problem instance

Two phases:

An **offline part** that performs at least  $O(|\mathcal{K}|)$  operations

An **online part** that attacks each of the  $L$  keys independently

An extreme example, **codebook dictionary**:

Offline:

1. choose block  $B$

2. create hash table with  $(Enc_K(B), K)$  entries

Complexity: Time  $O(|\mathcal{K}|)$ , Memory:  $O(|\mathcal{K}|)$

Online:

1. for each secret key  $K_i$  to be attacked

2. Query  $C = Enc_{K_i}(B)$

3. Find table entry  $(C, K_i)$

Complexity: Time  $O(1)$ , Memory:  $O(|\mathcal{K}|)$

Non-uniform attacks:

Another view on an attack with pre-computation

Make pre-computed data part of online attack algorithm

Online algorithm now only has total cost  $< O(|\mathcal{K}|)$

Such algorithms called **non-uniform**

# Hellman's Time-Memory trade off attack

An attack that uses more time, but less memory

Idea:

Use fixed block  $B$  and map  $\phi: \mathcal{C} \rightarrow \mathcal{K}$

Iterative function  $F: \mathcal{K} \rightarrow \mathcal{K}$  'walks' through key space

$$F(K_i) = K_{i+1}, \text{ where } C = \text{Enc}_{K_i}(B), K_{i+1} = \phi(C)$$

Offline: store many long walks covering key space

Only store begin and endpoints  $(SP_j, EP_j = F^t(SP_j))$

Online: query  $C_0 = \text{Enc}_K(B), K_0 = \phi(C_0)$

Note that:  $F(K) = K_0$  by definition

Walk from  $K_0$  until say endpoint  $EP_1$  is found

Find secret  $K$  by walking from  $SP_1$

# Hellman's Time-Memory trade off attack

## Setup Details:

$F: \mathcal{K} \rightarrow \mathcal{K}$ , where  $F = \phi \circ E$

$E: \mathcal{K} \rightarrow \mathcal{M}$ ,  $E(K) := Enc_K(B)$

$\phi: \mathcal{M} \rightarrow \mathcal{K}$  needs to be surjective

If  $|\mathcal{M}| \geq |\mathcal{K}|$  then easy, otherwise impossible

When  $|\mathcal{M}| < |\mathcal{K}|$

Use multiple blocks  $B_1, B_2, \dots, B_l$  such that  $|\mathcal{M}|^l \geq |\mathcal{K}|$

$E: \mathcal{K} \rightarrow \mathcal{M}^l$ ,  $E(K) := (Enc_K(B_1), \dots, Enc_K(B_l))$

And surjective map  $\phi: \mathcal{M}^l \rightarrow \mathcal{K}$

# Hellman's Time-Memory trade off attack

## Simplified version

### Attack parameters

Number of walks:  $m$

Length of each walk:  $t$

### Offline attack:

1. Choose  $SP_1, \dots, SP_m$  uniformly at random from  $\mathcal{K}$
2. Compute  $EP_i = F^t(SP_i)$  for  $i = 1, \dots, m$
3. Store  $(EP_i, SP_i)$  in hash table / sorted table

### Online attack:

1. Given  $C_0 = Enc_K(B)$  for some unknown key  $K$
2. Let  $P_0 = \phi(C_0)$
3. For  $i = 0, \dots, t - 1$
4. If  $P_i = EP_j$  for some  $j$  then
5. Let  $\tilde{K} := F^{t-i-1}(SP_j)$
6. If  $Enc_{\tilde{K}}(B) = C_0$  then return  $\tilde{K}$
7. Compute  $P_{i+1} := F(P_i)$
8. Otherwise, return  $\perp$

# Hellman's Time-Memory trade off attack

## Simplified version analysis

Ideally, use  $m \cdot t = |\mathcal{K}|$  and hope to cover entire space

Ideal situation

However,  $F$  behaves as a random function

Many collisions  $F(x) = F(y)$  exist and merges walks

Substantial part of space is never reached

Creates false alarms:

$K$  does not actually lie on walk from  $SP_i$ ,  
but on walk from another  $SP$  with same  $EP_i$

Expected situa  
random functi

# Hellman's Time-Memory trade off attack

## Simplified version analysis

Collisions start to occur when  $m \cdot t \approx \sqrt{|\mathcal{K}|}$

Due to the [birthday paradox](#) (covered later)

The expected number of collisions grows roughly quadratic in  $m \cdot t$

False alarms analysis:

Walk from  $P_0$  has  $t$  points

There are at most  $m \cdot t$  points covered by the table

Each pair has probability  $1/|\mathcal{K}|$  to collide and cause false alarm  
(i.e. without  $P_0$  actually being on the walk)

Expected number of false alarms:  $E[Z] \leq m \cdot t^2 / |\mathcal{K}|$

Expected costs of false alarm:  $t \cdot E[Z] \leq m \cdot t^3 / |\mathcal{K}|$

Success only if target  $K$  is covered (part of a walk from a  $SP_i$ )

Hellman: when  $m \cdot t^2 = |\mathcal{K}|$ , success probability is  $\approx 0.80mt/|\mathcal{K}|$

# Hellman's Time-Memory trade off attack

## Improved version

Use  $r$  independent tables with different  $\phi_1, \dots, \phi_r$

Even if the same key is covered in different tables  
then different  $\phi_i$  imply different walks instead of merging walks

Hellman proposed  $m = t = r = \sqrt[3]{|\mathcal{K}|}$

Individual table: success probability  $\approx 0.80 / \sqrt[3]{|\mathcal{K}|}$

Total success probability  $\approx 0.8$

Offline time complexity:  $O(mtr) = O(|\mathcal{K}|)$

Offline memory complexity:  $O(rm) = O(|\mathcal{K}|^{2/3})$

Online complexity:

$$O(rt + rmt^3/|\mathcal{K}|) = O(|\mathcal{K}|^{2/3} + |\mathcal{K}|^{2/3}) = O(|\mathcal{K}|^{2/3})$$
